Acid transactions are one of the most used software engineering techniques, A₁, 160; cornerstone of p~ 160; Relational databases, and an integral part of the middleware company where transactions are often offered as primitive black box. Despite all these and many other cases, the old-fashioned approach to transactions cannot be maintained in a variety of modern large-scale systems and NOSQL storage due to high performance needs, data volumes and availability. In such cases, traditional transactions are rarely replaced by a personalized model that presupposes the implementation of transactions in 194; 160; or semitransaction operations at the top of units that are not transactions alone; 1940; 160; In this post we take into consideration the implementation of transactions: transactions without blocking at the top of 194; 160; Key-Value Storage, although these techniques are generic and can be used in any system similar to databases. In GridDynamics, we recently used some of these techniques to implement a slight non-standard transaction on the top of Oracle Coherence. In the first section we take a look at two simple approaches that adapt to which 19; 160; IMPORTANT 194; 160; Use houses, in the second section we study a more generic approach that resembles PostgreSQL 226; 128; S MVCC implementation. Atomic cache Switching, Read \bar{a} , 160; Moved \bar{A} , 160; Isolation Let's start with simple and easy techniques from implement area that are intended for relatively rare updates in reading systems, for example, recharging daily data in ecommerce systems, administrative operations such as repair of invalid objects, or Refresh Cache. The most trivial case is to recharge all the data in the cache (or in the key space). Take the cache interface with a proxy that intercepts all the cache operations like GET () or PUT (). This proxy is supported by two caches, ie and B, and works according to the following simple logic (Fig.1): at any time, only one cache is active and proxy all user requests to it (Fig.1.1) Update process loading new data Inactive cache (Fig.1.2) refractive process moves a global flag shared by all proxies participating in refreshment and this flag \bar{a} 160; defines which cache is active (Fig.1.3). Proxy starts sending all new read transactions to the new active cache. operations under way at the time of 194; 160; switching can be managed in 194; 160; different (194; 160) depending on the required level of consistency and isolation, if unrepeatable reads are acceptable (some operations can read data in part from the old state and in part from the new) then the switch is simple and the old data can be cleaned immediately. Otherwise, the proxy should maintain a list of active operations and route each to the cache initially assigned, old data can only be purified when all related transactions have been committed or interrupted. Fig.1 cache switch the similar technique can be oata for partial updates, can be implemented in 194; 160; differently depends on 194; 160; according to 194; 160; storage, we want a simple three-cache strategy, the picture is similar to the previous one, but the proxy acts in the following way (Fig.2): user requests are addressed to the new and updated cache primary (Fig.2.1) are loaded in the cache again, the keys of the deleted items are stored in the deleted cache \bar{A} (Fig.2.2) the process of copying begins with the switching of the global flag. The flag instructs proxy to search for new and deleted cache keys before any user request is sent to the primary cache (Fig.2.3) in other words, user requests have changed to read data at this stage, the process of engagement begins to propagate changes from new and deleted cache to the primary cache one by one. After a non-committed transaction, the commit process returns the global flag and requests are referred to the old cache (Fig.2.4). Old data is copied to new cache during step 4 to ensure reliability. Oracle Coherence has implemented a more complex mechanism, Fig.1 Partial Cache Switch So, from the examples above, we can conclude that attaching the read transactions to the instant of the data and avoiding interference from the commitment of the update transactions is one of the main sources of complexity. This is obviously a case for intensive writing environments. In the next section we consider a powerful technique that helps to solve this problem gracefully, MVCC transactions, the isolation of the read-only isolation between transactions can be achieved using the version of separate elements in Key-Value space. There are several ways to implement this technique, here we discuss an approach that is very similar to how PostgreSQL handles transactions. As was said in the previous section, each transaction should be attached to a particular snapshot of the data that is a set of elements in the cache. At the same time, each element has its own life span from the moment it was added to the cache until it was removed or updated, i.e. replaced by a new version. Thus, isolation can be achieved by marking each item two timbers of time, each transaction within its starting time, and the control that the transaction sees only elements that were alive at the time of the transaction has begun. In practice, of course, global monotonous increasing meters are usually used instead of time stamps. More formally: When a new transaction is initiated, it is associated with its Transaction ID or XID which is unique for each transaction and grows monotonously. A XID list of all current transactions. Each element in the cache is marked with two values, xmin and xmax. The values are assigned as follows: When the element is created by a certain transaction, xmin is set to XID of transaction, xmax is empty. When the item is removed from a certain transaction, xmin is not changed, xmax is set to XID. The item is not actually removed from the cache, it is simply marked as deleted. When the item is updated by some some the old version is stored in the cache, its 160xmax fixed to XID; new version is inserted with xmin=XID and xmax empty. In other words, this is equivalent to removing + insert. The goods are visible for operation with XID = txide 160; if the following two statements are true, xmin is a XID of the committed operation and 160xmin is less than or equal to txid xmax is empty, or XID of the non-committed (aborted or ongoing) transaction; Oro 160; Each xmin and xmax can store two bit flags indicating where the operation was interrupted or committed to perform the controls described in the previous point. This 194; 160? The logic is illustrated in the following graphics: Fig.3 PostgreSQL-like MVCC The disadvantage of this approach is a rather complex procedure of removing outdated versions. Because \odot different operations will have visibility to different elements and versions, it is not easy to determine a time when a particular version becomes invisible and can be deleted. There are at least two different techniques to do this, the first is used in PostgreSQL, the second in the Oracle Database: 160; All versions are stored in the same key value space and there is no fixed limit on how many versions can be maintained. The old versions are collected from a background 160; the process being carried out 160; continuous, by program, or triggered by reading or writing. The primary key space stores only the latest versions, the previous versions are stored in another fixed-size repository. The latest versions have references to previous versions and a particular version can be traced from transactions that require them. Poiche. \odot the storage size is limited, the oldest versions can be removed to the free space for the article. If a transaction is unable to find a requested version, it fails. Fails.
